# Introduction

Classical framework: Black-Scholes or Bachelier  $\rightarrow$  frictionless market, price-taker agent

- Continuous trading
- Pricing using a risk-neutral expectation
- Replicating portfolio
- Replicating strategy given by the  $\Delta$  of the option

## Liquidity-related questions:

- options written on illiquid assets?

# Framework

Model:

- Continuous time modelling
- Almgren-Chriss-like market impacts
- Expected utility framework (CARA)
- Indifference pricing
- Partial differential equation (viscosity solutions of HJB)

Features:

- Market impact and execution costs
- Partial hedge
- Modelling Physical delivery

# Call Option

**We consider that we have sold this call option with physical settlement.**

## Characteristics of the Call option

- Strike  $K$
- Maturity  $T$
- Nominal  $N$  (in shares)

# Call Option

**We consider that we have sold this call option with physical settlement.**

## Characteristics of the Call option

- Strike  $K$

# Call Option

- Maturity  $T$

# Call Option

**We consider that we have sold this call option with physical settlement.**

## Characteristics of the Call option

- Strike  $K$
- Maturity  $T$
- Nominal  $N$  (in shares)

# Call Option

**We consider that we have sold this call option with physical settlement.**

## Characteristics of the Call option

- Strike  $K$
- Maturity  $T$
- Nominal  $N$  (in shares)

*$N$  matters because the introduction of execution costs and market impact makes the problem a non-linear one.*

# Notations

- Let  $(\Omega, \mathbb{F}, (\mathcal{F}_t)_{t \geq 0}, \mathbb{P})$  be a filtered probability space
- The number of shares in the hedging portfolio

$$q_t = q_0 + \int_0^t v_s ds,$$

where  $q_0$  denotes the number of shares in the portfolio at inception

- The process  $(v)$  lies in the admissible set:

$$\mathcal{A} = \left\{ v \in \mathcal{P}(0, T), \int_0^T |v_t| dt \in L^\infty(\Omega) \right\}$$

where  $\mathcal{P}(s, t)$  is the set of  $\mathbb{R}$ -valued progressively measurable processes on  $[s, t]$

## Permanent Market Impact

We could consider the classical linear model:

### Linear Permanent Market Impact Model

$$dS_t = \sigma dW_t + kv_t dt$$

Here we consider the more general framework:

### General Permanent Market Impact Model

$$dS_t = \sigma dW_t + f(|q_0 - q_t|) v_t dt$$

where  $f : \mathbb{R}_+^* \rightarrow \mathbb{R}_+$  nonincreasing and in  $L_{loc}^1(\mathbb{R}_+)$ .

## Instantaneous Market Impact (Execution costs)

### Execution Costs Function

Execution costs are modeled by  $L \in C(\mathbb{R}, \mathbb{R}_+)$  verifying:

- $L(0) = 0$
- $L$  is an even function
- $L$  is increasing on  $\mathbb{R}_+$
- $L$  is strictly convex
- $L$  is asymptotically superlinear:  $\lim_{\rho \rightarrow +\infty} \frac{L(\rho)}{\rho} = +\infty$

## Instantaneous Market Impact (Execution costs)

### Execution Costs Function

Execution costs are modeled by  $L \in C(\mathbb{R}, \mathbb{R}_+)$  verifying:

- $L(0) = 0$
- $L$  is an even function
- $L$  is increasing on  $\mathbb{R}_+$
- $L$  is strictly convex
- $L$  is asymptotically superlinear:  $\lim_{\rho \rightarrow +\infty} \frac{L(\rho)}{\rho} = +\infty$

### In practice

$L$  is a function of the following form:

$$L(\rho) = \eta |\rho|^{1+\phi} + \psi |\rho|$$

## Instantaneous Market Impact (Execution costs)

### Impact on Cash

The Cash account  $X$  evolves as:

$$dX_t = -v_t S_t dt - V_t L \left( \frac{v_t}{V_t} \right) dt, \quad X_0 = 0$$

where the process  $(V_t)_t$  is the market volume process, assumed to be deterministic, positive and bounded.

  - Comparative Statics

# Payoff

We assume physical settlement. The payoff is then given by the following rule:

# Payoff

We assume physical settlement. The payoff is then given by the following rule:

- If the option is exercised:

$$\underbrace{X_T}_{\text{cash account}} + \underbrace{KN}_{\text{payment of the client}} - \underbrace{((N - q_T)S_T + \mathcal{L}(q_T, N))}_{\text{cost of buying } (N - q_T) \text{ shares}}$$

where  $\mathcal{L}(q, q')$  models costs at time  $T$  to go from a portfolio with  $q$  shares to a portfolio with  $q'$  shares.

# Payoff

We assume physical settlement. The payoff is then given by the following rule:

- If the option is exercised:

$$\underbrace{X_T}_{\text{cash account}} + \underbrace{KN}_{\text{payment of the client}} - \underbrace{((N - q_T)S_T + \mathcal{L}(q_T, N))}_{\text{cost of buying } (N - q_T) \text{ shares}}$$

where  $\mathcal{L}(q, q')$  models costs at time  $T$  to go from a portfolio with  $q$  shares to a portfolio with  $q'$  shares.

- Otherwise, the payoff is:

$$\underbrace{X_T}_{\text{cash account}} + \underbrace{q_T S_T - \mathcal{L}(q_T, 0)}_{\text{gain of selling the } q_T \text{ shares}}$$

# Payoff

The payoff can then be written as (the threshold is assumed to be  $K' \leq K$ ):

Payoff

$$X_T + q_T S_T + 1_{S_T \geq K'} (N(K - S_T) - \mathcal{L}(q_T, N)) - 1_{S_T < K'} \mathcal{L}(q_T, 0)$$

# Payoff

The payoff can then be written as (the threshold is assumed to be  $K' \leq K$ ):

## Payoff

$$X_T + q_T S_T + 1_{S_T \geq K'} (N(K - S_T) - \mathcal{L}(q_T, N)) - 1_{S_T < K'} \mathcal{L}(q_T, 0)$$

To ensure the absence of dynamic arbitrage, we specify  $\mathcal{L}$  as:

$$\mathcal{L}(q, q') = \ell(q' - q) + q'(G(q') - G(q)) - (F(q') - F(q))$$

where  $\ell$  is the cost function when there is no permanent market impact,  $F(q) = \int_{q_0}^q z f(|q_0 - z|) dz$  and  $G(q) = \int_{q_0}^q f(|q_0 - z|) dz$ .

# Optimization Problem

## Optimization Problem

The bank maximizes its expected utility:

$$\sup_{v \in \mathcal{A}} \mathbb{E} \left[ - \exp \left( - \gamma \left( X_T + q_T S_T + 1_{S_T \geq K'} (N(K - S_T) - \mathcal{L}(q_T, N)) - 1_{S_T < K'} \mathcal{L}(q_T, 0) \right) \right) \right]$$

where  $\gamma$  is the absolute risk aversion parameter of the bank.

This framework permits to define a price for the option using indifference pricing.

# Value Function

To solve this problem, we introduce the value function  $u$ :

## Definition

$$\begin{aligned}
 u(t, x, q, S) = & \sup_{v \in \mathcal{A}_t} \mathbb{E} \left[ -\exp \left( -\gamma \left( X_T^{t,x,v} + q_T^{t,q,v} S_T^{t,S,v} \right. \right. \right. \\
 & \left. \left. \left. + 1_{S_T^{t,S,v} \geq K'} \left( N(K - S_T^{t,S,v}) - \mathcal{L}(q_T^{t,q,v}, N) \right) \right. \right. \right. \\
 & \left. \left. \left. - 1_{S_T^{t,S,v} < K'} \mathcal{L}(q_T^{t,q,v}, 0) \right) \right) \right],
 \end{aligned}$$

where  $\mathcal{A}_t = \left\{ v \in \mathcal{P}(t, T), \int_t^T |v_s| ds \in L^\infty(\Omega) \right\}$ .

# HJB Equation

$u$  satisfies the following HJB equation:

HJB equation

$$-\partial_t u - \frac{1}{2} \sigma^2 \partial_{SS}^2 u - \sup_{v \in \mathbb{R}} \left\{ v \partial_q u + \left( -vS - L \left( \frac{v}{V_t} \right) V_t \right) \partial_x u - \partial_S u f(|q_0 - q|) v \right\} = 0$$

with terminal condition:

$$u(T, x, q, S) = - \exp \left( - \gamma \left( x + qS - 1_{S < K'} \mathcal{L}(q, 0) + 1_{S \geq K'} (N(K - S) - \mathcal{L}(q, N)) \right) \right)$$

  - Comparative Statics

# Change of Variables

We use the following change of variables:

## Definition

We introduce  $\theta$  by:

$$u(t, x, q, S) = -\exp(-\gamma(x + qS - F(q) - \theta(t, q, S - G(q))))$$

## Change of Variables

We use the following change of variables:

### Definition

We introduce  $\theta$  by:

$$u(t, x, q, S) = -\exp(-\gamma(x + qS - F(q) - \theta(t, q, S - G(q))))$$

### Indifference Price

$\theta(0, q_0, S_0)$  is the indifference price to write the call option.

## PDE for $\theta$

The PDE satisfied by  $\theta$  is the following:

PDE

$$-\partial_t \theta - \frac{1}{2} \sigma^2 \partial_{\tilde{S}}^2 \theta - \frac{1}{2} \gamma \sigma^2 (\partial_{\tilde{S}} \theta - q)^2 + V_t H(\partial_q \theta) = 0$$

where  $H$  is the Legendre transform of  $L$ :

$$H(p) = \sup_{\rho} \{p\rho - L(\rho)\}$$

Terminal condition:

$$\begin{aligned} \theta(T, q, \tilde{S}) = & 1_{\tilde{S} \geq K' - G(q)} \left( N(\tilde{S} - K) + NG(N) - F(N) \right. \\ & \left. + \ell(N - q) \right) + 1_{\tilde{S} < K' - G(q)} (\ell(q) - F(0)) \end{aligned}$$

# PDE

Interpretation of the PDE:

$$\underbrace{-\partial_t \theta - \frac{1}{2} \sigma^2 \partial_{\bar{S}\bar{S}}^2 \theta}_{\text{Diffusion}} - \underbrace{\frac{1}{2} \gamma \sigma^2 (\partial_{\bar{S}} \theta - q)^2}_{\text{"Mishedge"}} + \underbrace{V_t H(\partial_q \theta)}_{\text{Execution costs}} = 0$$

An optimal control is given by:

Optimal Control

$$v^*(t, q, S) = H'(\partial_q \theta(t, q, S - G(q)))$$

## Reference Scenario

- $S_0 = K = K' = 45 \text{ €}$
- $\sigma = 0.6 \text{ €} \cdot \text{day}^{-1/2}$  ( $\approx 21\%$  annual volatility)
- $T = 60 \text{ days}$
- $V = 1\,000\,000 \text{ shares} \cdot \text{day}^{-1}$
- $V_d = 1\,000\,000 \text{ shares}$
- $N = 5\,000\,000 \text{ shares}$
- $L(\rho) = \eta |\rho|^{1+\phi}$  with  $\eta = 0.1 \text{ €} \cdot \text{shares}^{-1} \cdot \text{day}^{-1}$  and  $\phi = 0.75$
- $\gamma = 10^{-6} \text{ €}^{-1}$

## Reference Scenario 1 (No PMI)

# Importance of Initial Position

Figure: Optimal portfolio when prices follow trajectory 1

# Importance of Initial Position

Figure: Optimal portfolio when prices follow trajectory 2

# Importance of Initial Position

The prices are given by:

|   | $q_0 = 0$ | $\frac{q_0}{N} = 0.5$ |
|---|-----------|-----------------------|
| Price of the call                       | 2.54      | 2.19                  |
| Implied $\sigma$ in the Bachelier model | 0.82      | 0.71                  |

Building the initial position in  $\Delta$  is usually costly.

- 2 Optimization Problem
  - Payoff
  - Optimization Problem
  - Change of Variables
- 3 Numerical Experiments
  - Reference Scenario
  - Importance of Initial Position
  - **Effect of Permanent Impact**
  - Comparative Statics

## Effect of Permanent Impact

We add the following permanent impact:

### Permanent Impact

$f$  is now defined as:

$$f(q) = 0.001 \frac{1}{\sqrt{|q|}}$$

## Trajectory 1 - Strategies

Figure: Optimal portfolio when prices follow trajectory 1

## Trajectory 1 - Impacted Prices

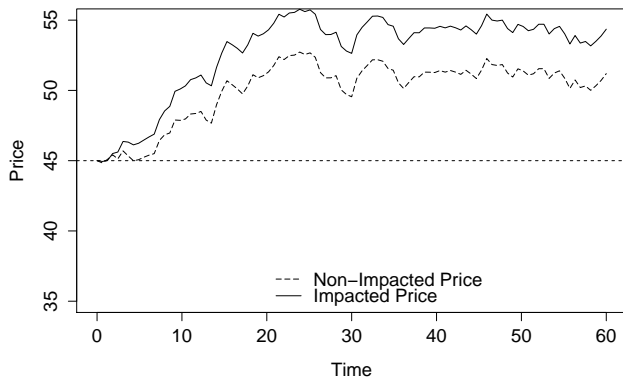

Figure: Prices (trajectory 1) with the influence of permanent market impact

## Trajectory 2 - Strategies

Figure: Optimal portfolio when prices follow trajectory 2

## Trajectory 2 - Impacted Prices

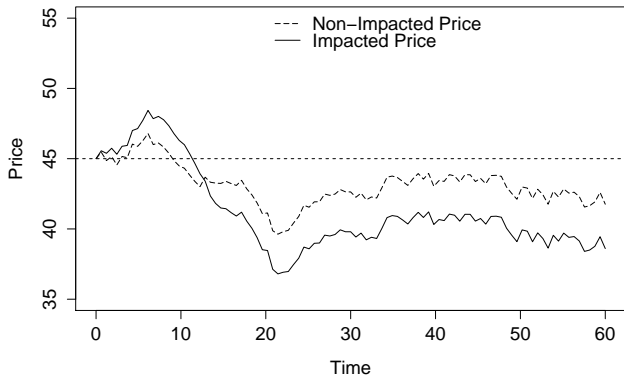

Figure: Prices (trajectory 2) with the influence of permanent market impact

## Effect of Permanent Impact

- Mechanical effect: if the price goes up (resp. down), our position goes up (resp. down), and it pushes the price up (resp. down).
- Strategical effect: near maturity and near the money, the bank has incentives to sell shares to push down the price so that the option expires worthless.

## Execution Costs

Figure: Optimal portfolio for different values of  $\eta$ , when prices follow Trajectory 1

## Execution Costs

Figure: Optimal portfolio for different values of  $\eta$ , when prices follow Trajectory 2

## Execution Costs

When  $\eta$  increases:

- The trajectories are smoother
- They are closer to the position  $0.5N$  to avoid round trips

When  $\eta \rightarrow 0$ , we obtain the limiting case of  $\Delta$ -Hedging.

The prices are given by:

| $\eta$                                | 0.2  | 0.1  | 0.05 | 0.01 | 0 (Bachelier) |
|---------------------------------------|------|------|------|------|---------------|
| Price of the call                     | 2.36 | 2.19 | 2.07 | 1.92 | 1.85          |
| Implied $\sigma$ in a Bachelier model | 0.76 | 0.71 | 0.67 | 0.62 | 0.6           |

- Prices are higher when  $\eta$  increases.
